

Problem 1

A logistic regression model predicts the probability of a student passing an exam:

$$P(y = 1|x) = \frac{1}{1 + e^{-(0.5x+0.2)}}$$

Here x is hours studied.

- What is the probability of passing if a student studies 2 hours?
 - What is the decision boundary value of x (where probability = 0.5)?
-

Problem 2

Given a single data point: actual $y = 1$, predicted probability $\hat{y} = 0.3$.
Calculate the **Log Loss** for this single example.

Problem 3

You train a logistic regression model with weight $w = 2.0$ and bias $b = -1.0$.

For a feature vector $x = [1.5, 0.5]$,

- Compute $z = w \cdot x + b$
 - Compute the predicted probability $\hat{y} = \sigma(z)$.
 - If actual $y = 1$, should the model update w to increase or decrease? Brief some reasoning
-

Problem 4

A logistic regression model gives the following probabilities for 5 test samples:

[0.1, 0.4, 0.6, 0.9, 0.45]

Actual labels: [0, 0, 1, 1, 0]

Using threshold = 0.5:

- Find predicted classes.
 - Calculate accuracy.
 - How many false positives and false negatives?
-

Problem 5

A logistic regression model is trained on a dataset with 2 features.

The learned parameters are: $w = [1.2, -0.8]$, $b = 0.5$.

- Write the equation of the decision boundary.
 - A new point has $x_1 = 2.0$, $x_2 = 1.5$. Which class is predicted?
 - How far (in terms of z value) is this point from the decision boundary?
-

Problem 6

You are given a highly imbalanced dataset: 95% negative class (0) and 5% positive class (1).

You train a logistic regression model and get 95% accuracy, but it predicts all samples as class 0.

- Why is accuracy misleading here?
- Which evaluation metric(s) would you use instead?

c) How can you adjust the model to detect more positive samples?

Problem 7

Write **pseudocode** (or Python-like logic) for the following functions in logistic regression from scratch (no libraries except numpy for basic ops):

- a) sigmoid(z)
- b) predict_probability(X, w, b)
- c) compute_cost(X, y, w, b)
- d) compute_gradients(X, y, w, b)
- e) gradient_descent($X, y, w_{\text{init}}, b_{\text{init}}, \alpha, \text{iterations}$)

Focus on the loops and formulas, not exact Python syntax.
